

Purpose: To calculate the speed of sound in air, and to understand resonance.

Procedure: Take a tuning fork, start it vibrating **** ONLY USING RUBBER STARTER **** and hold it over the top of your tube. Slowly lower the volume of water until you achieve a resonant situation. Measure the height of the air column. Repeat for a different tuning fork. Find out air temperature and column diameter. Cleanup & calculate.

Results/Questions:

Data/Calculations:		
Trial	One	Two
Frequency of fork (Hz) (f)		
Measured Resonant Length (cm)		
Corrected length (m) (unit change!)		
Corrected full wavelength (m) (λ)		
Calculated Velocity of sound (m/s) (v)		
% difference		

Air Temperature:	°C
Column Diameter:	cm

1. The column length is corrected because the air just above the column vibrates as if it was in the tube. Put your answer in the calculations table.

$$\text{Corrected length} = \text{Measured length} + .4 \times \text{tube diameter}$$

<-----

2. How much of a wavelength does resonance #1 represent? Why?

3. Calculate the speed of sound using $v = f \lambda$ and put it in the table.

4. To calculate the actual speed of sound, use the following formula:

$$v_{\text{actual}} = 331 + .6 T$$

$$v_{\text{actual}} = \text{_____} \text{ m/s}$$

5. Calculate % difference and place in calculations table.

$$\frac{(\text{Actual} - \text{Calculated})}{\text{Actual}} * 100$$

6. What other wavelength portions could you use to get resonance using this setup?

--	--	--

7. What is the smallest length tube you need to hear your fundamental resonance if the air temperature was 120 degrees and you used a 279 Hz tuning fork?
